ABSTRACT

The transputer is a programmable VLSI device with communication links for point-to-point connection to other transputers. Occam (*) is a language which enables a transputer system to be described as a collection of processes which operate concurrently and communicate through named channels. This paper describes how the transputer implements the communicating processes of occam, providing an efficient implementation of concurrency and message passing in a distributed system.

1 INTRODUCTION

The occam programming language enables an application to be described as a collection of processes which operate concurrently and communicate through channels. In such a description, each occam process describes the behavior of one component of the implementation, and each channel describes a connection between components.

The design of occam allows the components and their connections to be implemented in many different ways. This allows the choice of implementation technique to be chosen to suit available technology, to optimise performance, or to minimise cost.

VLSI technology allows a large number of identical devices to be manufactured cheaply. For this reason, it is attractive to implement an occam program using a number of identical components, each programmed with the appropriate occam process. A transputer is such a component.

The transputer can therefore be used as a building block for fifth generation systems, with occam as the associated design formalism.

2 ARCHITECTURE

An important property of VLSI technology is that communication between devices is very much slower than communication on the same device. In a computer, almost every operation that the processor performs involves the use of memory. A transputer therefore includes both processor and memory in the same integrated circuit device.

In any system constructed from integrated circuit devices, much of the physical bulk arises from connections between devices. The size of the package for an integrated circuit is determined more by the number of connection pins than by the size of the device itself. In addition, connections between devices provided by paths on a circuit board consume a considerable amount of space.

The speed of communication between electronic devices is optimised by the use of one-directional signal wires, each connecting two devices. If many devices are connected by a shared bus, electrical problems of driving the bus require that the speed is reduced. Also, additional control logic and wiring is required to control sharing of the bus.

To provide maximum speed with minimal wiring, the transputer uses point-to-point serial communication links for direct connection to other transputers.

3 OCCAM

Occam enables a system to be described as a collection of concurrent processes, which communicate with each other and with peripheral devices through channels. Occam programs are built from three primitive processes:

\[ \begin{align*}
    v & := e \quad \text{assign expression } e \text{ to variable } v \\
    c \rightarrow e & \quad \text{output expression } e \text{ to channel } c \\
    c ? v & \quad \text{input from channel } c \text{ to variable } v
\end{align*} \]

The primitive processes are combined to form constructs:

- **Sequential**: components executed one after another
- **Parallel**: components executed together
- **Alternative**: component first ready is executed

A construct is itself a process, and may be used as a component of another construct.

Conventional sequential programs can be expressed with variables and assignments, combined in sequential constructs. IF and WHILE constructs are also provided.

Concurrent programs can be expressed with channels, inputs and outputs, which are combined in parallel and alternative constructs.

Each occam channel provides a communication path between two concurrent processes. Communication is synchronised and takes place when both the inputting process and the outputting process are ready. The data to be output is then copied from the outputting process to the inputting process, and both processes continue.

An alternative process may be ready for input from any one of a number of channels. In this case, the input is taken from the channel which is first used for output by another process.

The benefits of point-to-point communication have already been mentioned above. The choice of synchronised communication simplifies programming as it prevents the loss of data. The choice of unbuffered communication removes the need for any stores to be associated with the channel. Copying data from the outputting process to the inputting process is clearly essential for communication between transputers, and has significant additional performance advantages. It is easy to make copying within a machine fast by use of microcode.

4 THE TRANSPUTER

A transputer system consists of a number of interconnected transputers, each executing an occam process and communicating with other transputers. As a process executed by a transputer may itself consist of a number of concurrent processes the transputer has to support the occam programming model internally. Within a transputer concurrent processing is implemented by sharing the processor time between the concurrent processes.

The most effective implementation of simple programs by a programmable computer is provided by a sequential processor. Consequently, the transputer processor is fairly conventional, except that additional hardware and microcode support the occam model of concurrent processing.

4.1 Sequential Processing

The design of the transputer processor exploits the availability of fast on-chip memory by having only a small number of registers; six registers are used in the execution of a sequential process. The small number of registers, together with the simplicity of the instruction set enables the processor to have relatively simple (and fast) data-paths and control logic.

The six registers are:

- The workspace pointer which points to an area of store where local variables are kept.
- The instruction pointer which points to the next instruction to be executed.
The operand register which is used in the formation of instruction operands.

The A, B and C registers which form an evaluation stack, and are the sources and destinations for most arithmetic and logical operations. Loading a value into the stack pushes B into C, and A into B, before loading A. Storing a value from A, pops B into A and C into B.

Expressions are evaluated on the evaluation stack, and instructions refer to the stack implicitly. For example, the 'add' instruction adds the top two values in the stack and places the result on the top of the stack. The use of a stack removes the need for instructions to respecify the location of their operands. Statistics gathered from a large number of programs show that three registers provide an effective balance between code compactness and implementation complexity.

4.2 Instructions

It was a design decision that the transputer should be programmed in a high-level language. The instruction set has, therefore, been designed for simple and efficient compilation. It contains a relatively small number of instructions, all with the same format, chosen to give a compact representation of the operations most frequently occurring in programs. The instruction set is independent of the processor wordlength, allowing the same microcode to be used for transputers with different wordlengths. Each instruction consists of a single byte divided into two 4 bit parts. The four most significant bits of the byte are a function code, and the four least significant bits are a data value.

<table>

<td>0</td>
</tr>
</tbody>
</table>

4.2.1 Direct functions

The representation provides for sixteen functions, each with a data value ranging from 0 to 15. Thirteen of these are used to encode the most important functions performed by any computer. These include:

- load constant
- add constant
- load local
- store local
- load local pointer
- load non-local
- store non-local
- jump
- conditional jump
- call

The most common operations in a program are the loading of small literal values, and the loading and storing of one of a small number of variables. The 'load constant' instruction enables values between 0 and 15 to be loaded with a single byte instruction. The 'load local' and 'store local' instructions access locations in memory relative to the workspace pointer. The first 16 locations can be accessed using a single byte instruction.

The 'load non-local' and 'store non-local' instructions behave similarly, except that they access locations in memory relative to the A register. Compact sequences of these instructions allow efficient access to data structures, and provide for simple implementations of the static
links or displays used in the implementation of block structured programming languages such as ocean.

4.2.2 Prefix functions

Two more of the function codes are used to allow the operand of any instruction to be extended in length. These are:

prefix
negative prefix

All instructions are executed by loading the four data bits into the least significant four bits of the operand register, which is then used as the the instruction's operand. All instructions except the prefix instructions and by clearing the operand register, ready for the next instruction.

```
Function | Data
```

The 'prefix' instruction loads its four data bits into the operand register, and then shifts the operand register up four places. The 'negative prefix' instruction is similar, except that it complements the operand register before shifting it up. Consequently operands can be extended to any length up to the length of the operand register by a sequence of prefix instructions. In particular, operands in the range -256 to 255 can be represented using one prefix instruction.

The use of prefix instructions has certain beneficial consequences. Firstly, they are decoded and executed in the same way as every other instruction, which simplifies and speeds instruction decoding. Secondly, they simplify language compilation, by providing a completely uniform way of allowing any instruction to take an operand of any size. Thirdly, they allow operands to be represented in a form independent of the processor wordlength.

4.2.3 Indirect functions

The remaining function code, 'operate', causes its operand to be interpreted as an operation on the values held in the evaluation stack. This allows up to 16 such operations to be encoded in a single byte instruction. However, the prefix instructions can be used to extend the operand of an 'operate' instruction just like any other. The instruction representation therefore provides for an indefinite number of operations.

The encoding of the indirect functions is chosen so that the most frequently occurring operations are represented without the use of a prefix instruction. These include arithmetic, logical and comparison operations such as

add
exclusive or
greater than

Less frequently occurring operations have encodings which require a single prefix operation (the transputer instruction set is not large enough to require more than 512 operations to be encoded).

4.2.4 Efficiency of Encoding

Measurements show that about 80% of executed instructions are encoded in a single byte (i.e., without the use of prefix instructions). Many of these instructions, such as 'load constant' and 'add' require just one processor cycle.

The instruction representation gives a more compact representation of high level language programs than more conventional instruction sets. Since a program requires less store to represent it, less of the memory bandwidth is taken up with fetching instructions. Furthermore, as memory is word accessed the processor will receive several instructions for every fetch.

Short instructions also improve the effectiveness of instruction prefetch, which in turn improves processor performance. There is an extra word of prefetch buffer so that the processor rarely has to wait for an instruction fetch before
proceeding. Since the buffer is short, there is little time penalty when a jump instruction causes the buffer contents to be discarded.

4.1 Support for Concurrency

The processor provides efficient support for the ocaml model of concurrency and communication. It has a microcoded scheduler which enables any number of concurrent processes to be executed together, sharing the processor time. This removes the need for a software kernel. The processor does not need to support the dynamic allocation of storage as the ocaml compiler is able to perform the allocation of space to concurrent processes.

At any time, a concurrent process may be

active - being executed
  - on a list awaiting execution
inactive - ready to input
  - ready to output
  - waiting until a specified time

The active processes waiting to be executed are held on a list. This is a linked list of process workspaces, implemented using two registers, one of which points to the first process on the list, the other to the last.

In this illustration, S is executing, and P, Q and R are active, awaiting execution.

A process is executed until it is unable to proceed because it is waiting to input or output, or waiting for the timer. Whenever a process is unable to proceed, its instruction pointer is saved in its workspace and the next process is taken from the list. Actual process switch times are very small as little state needs to be saved; it is not necessary to save the evaluation stack on rescheduling.

The processor provides a number of special operations to support the process model. These include:

start process
end process

When a parallel construct is executed, 'start process' instructions are used to create the necessary concurrent processes. A 'start process' instruction creates a new process by adding a new workspace to the end of the scheduling list, enabling the new concurrent process to be executed together with the ones already being executed.

The correct termination of a parallel construct is assured by use of the 'end process' instruction. This uses a workspace location as a counter of the components of the parallel construct which have still to terminate. When the components have all terminated, the counter reaches zero, and a specified process can then proceed.

4.4 Communications

Communication between processes is achieved by means of channels. Ocaml communication is point-to-point, synchronised and unbuffered. As a result, a channel needs no message queue, no process queue and no message buffer.

A channel between two processes executing on the same transputer is implemented by a single word in memory; a channel between processes executing on different transputers is implemented by point-to-point links. The processor provides a number of operations to support message passing, the most important being:

input message
output message
The 'input message' and 'output message' instructions use the address of the channel to determine whether the channel is internal or external. This means that the same instruction sequence can be used for both hard and soft channels, allowing a process to be written and compiled without knowledge of where its channels are connected.

As in the occam model, communication takes place when both the inputting and outputting processes are ready. Consequently, the process which first becomes ready must wait until the second one is also ready.

A process performs an input or output by loading the evaluation stack with a pointer to a message, the address of a channel, and a count of the number of bytes to be transferred, and then executing an 'input message' or an 'output message' instruction.

### 4.4.1 Internal Channel Communication

At any time, an internal channel (a word in memory) either holds identity of a process, or holds the special value 'empty'. The channel is initialised to 'empty' before it is used. When a message is passed using the channel, the identity of the first process to become ready is stored in the channel, and the processor starts to execute the next process from the scheduling list. When the second process uses the channel becomes ready, the message is copied, the waiting process is added to the scheduling list, and the channel is reset to its initial state. It does not matter whether the inputting or the outputting process becomes ready first.

In the following illustration, a process P is about to execute an output instruction on an 'empty' channel C. The evaluation stack holds a pointer to a message, the address of channel C, and a count of the number of bytes in the message.
The message is copied, the waiting process P is added to the scheduling list, and the channel C reset to its initial 'empty' state.

**WORKSPACE**

Next Inst → Empty

**4.4.2 External Channel Communication**

When a message is passed via an external channel, the processor delegates to an autonomous link interface the job of transferring the message and deschedules the process. When the message has been transferred the link interface causes the processor to reschedule the waiting process. This allows the processor to continue the execution of other processes whilst the external message transfer is taking place.

Each link interface uses three registers:

- a pointer to a process workspace
- a pointer to a message
- a count of bytes in the message

In the following illustration, processes P and Q executed by different transputers communicate using a channel C implemented by a link connecting the two transputers. P outputs, and Q inputs.
The message is now copied through the link, after which the workspaces of P and Q are returned to the corresponding scheduling lists. The protocol used on the link ensures that it does not matter which of P and Q first becomes ready.

\[
\begin{array}{c|c}
\text{P WORKSPACE} & \text{Q WORKSPACE} \\
\hline
\text{Next Inst} & \text{Next Inst} \\
\text{List} & \text{List}
\end{array}
\]

4.4.3 Alternative and Timer

The occam alternative construct enables a process to wait for input from any one of a number of channels, or until a specific time occurs. This requires special instructions, as the normal 'input' instruction deschedules a process until a specific channel becomes ready. The instructions used are:

- enable channel
- enable timer
- disable channel
- disable timer
- alternative wait

The alternative is implemented by 'enabling' the channel input or timer input specified in each of its components. The 'alternative wait' is then used to deschedule the process until one of the channel or timer inputs becomes ready, whereupon the process is scheduled again. The channel and timer inputs are then 'disabled'. The 'disable' instructions are also designed to select the component of the alternative to be executed.

4.5 Inter-transputer Links

A link between two transputers provides a pair of occam channels, one in each direction. A link between two transputers is implemented by connecting a link interface on one transputer to a link interface on the other transputer by two one-directional signal lines. Each signal line carries data and control information.

Communication through a link involves a simple protocol, which provides the synchronised communication of occam. The use of a protocol providing for the transmission of an arbitrary sequence of bytes allows transputers of different wordlength to be connected.

Each message is transmitted as a sequence of single byte communications, requiring only the presence of a single byte buffer in the receiving transputer to ensure that no information is lost. Each byte is transmitted as a start bit followed by a one bit followed by the eight data bits followed by a stop bit. After transmitting a data byte, the sender waits until an acknowledgement is received; this consists of a start bit followed by a zero bit. The acknowledgement signifies both that a process was able to receive the acknowledged byte, and that the receiving link is able to receive another byte. The sending link reschedules the sending process only after the acknowledgement for the final byte of the message has been received.

\[
\begin{array}{c|c|c|c}
1 & 1 & \text{Data} & 0 \\
\end{array}
\]

Data byte

\[
\begin{array}{c|c}
1 & 0 \\
\end{array}
\]

Acknowledge

Data bytes and acknowledgements are multiplexed on each signal line. An acknowledgement is transmitted as soon as reception of a data byte starts (if there is room to buffer another one). Consequently transmission may be continuous, with no delays between data bytes.
5 SUMMARY

Experience with occam has shown that many applications naturally decompose into a large number of fairly simple processes. Once an application has been described in occam, a variety of implementations are possible. In particular, the use of occam together with the transputer enables the designer to exploit the performance and economics of VLSI technology. The concurrent processing features of occam can be efficiently implemented by a small, simple and fast processor.

The transputer therefore has two important uses. Firstly it provides a new system 'building block' which enables occam to be used as a design formalism. In this role, occam serves both as a system description language and a programming language. Secondly, occam and the transputer can be used for prototyping highly concurrent systems in which the individual processes are ultimately intended to be implemented by dedicated hardware.
